# U pdate of length－based VPA in 2004 <br> Hiroyuki Kurota and Norio Takahashi <br> National Research Institute of Far Seas Fisheries， Shizuoka，J apan 

#### Abstract

We updated a VPA model based on catch－at－length data for SBT，which had been originally developed for the 2001 SAG meeting．Recruitment was estimated in each year by sequentially calculating population dynamics at half－year interval，when growth of SBT was assumed to depend on length and age．Length－based CPUE of $J$ apanese longline and age composition of Indonesian fishery on the spawning ground were used for tuning the model．

The analyses showed that recruitment estimates had dedining trend from 1970 to mid－1980s，and afterward they were roughly stable．However，they dropped to very low levels after 1999．Estimated spawning biomass showed decreasing trend after fishing started，but it was generally constant these ten years．We also conducted sensitivity analysis with regard to some parameters and examined influences of historical data update．

## 体長データに基づくVPA の2004年におけるアップデート

黑田啓行 高橋紀夫 遠洋水産研究所）

要旨：体長別漁獲尾数に基づいたVPA モデルのアップデートを行った。このモデルはもともと 2001 年 SAG のために開発されたものである。ミナ ミマグロの成長は体長と年齢に依存するという仮定のもと，半年毎に個体群動態を計算し，毎年の加入量を推定した。チューニングには，日本延縄の体長別 CPUE と産卵場でのインドネシア漁業の年齢構成のデータを用いた。

解析の結果，ミナミマグロの加入は，1970年以降1980年代半ばまで減少し，その後安定していたが，1999年以降かなり低い水準にあることが示された。親魚資源量のルントは漁獲開始以降，減少傾向にあったが，近年は比較的安定していることか明らかになった。いくつかのパラ メータに関する感度分析の結果，および過去の漁獲データの変更の影響などについても考察を行 った。

## Introduction

The ADAPT VPA currently used for SBT had some problems; overdependence of results on assumptions of plus group and inconsistency in CPUE trends between young ages and plus group. We considered that these problems resulted from cohort slicing used to make catch-at-age data, and developed this assessment model with catch-at-length (CAL) for the 2001 SAG meeting, although all the problems were not solved. To overcome the problems, some statistical models considering error of catch-at-age data, selectivity changes and so on have also been developing for SBT. However, they have too many assumptions to check each influence and their performance is not always acceptable. Thus, we consider that it is valuable to maintain a range of alternative assessment results, as the 2003 SAG meeting recommended (Anonymous, 2003), and updated this length-based VPA model.

After the previous stock assessment in 2001, several data were revised and added and our model formulation was also modified. The major differences are as follows:
a) revision of historical catch-at-age data and CPUE of J apanese longline (from 1965 to 2000; Tsuji et al., 2004)
b) addition of three years data of all fisheries (from 2001 to 2003)
c) recal culation of Indonesian catch data (from 1976 to 2003)
d) addition of a penalty term for yearly variation of recruitments to the objective function
e) change of mature age from 8 to 10 corresponding to the operating model used for the MP evaluation.
This report represents updated estimation result and results of sensitivity analysis corresponding to different model assumptions and input data.

## Model structure

## - Population dynamics

One year is assumed to consist of two fishery seasons to distinguish qualitatively different fisheries. Fishing is treated as a one-day pulse event. Australian surface fishery and Indonesian spawning ground fishery harvest on J anuary 1, and J apanese longline and miscellaneous fisheries on J uly 1 . Fish growth depends on both length and age and natural mortality depends on age. Recruitment occurs on J anuary 1 at length 0 cm . This model is a type of forward VPA model and it estimates recruitment number in each year as parameters using the AD model builder (Otter Research Ltd., 2001).

First season. Australian surface fishery and Indonesian spawning ground fishery are assumed to harvest SBT on J anuary 1. Population change by harvest is described as

$$
\begin{equation*}
N^{\prime}(l, y, r)=N_{1}(l, y, r)-\frac{N_{1}(l, y, r)}{\sum_{r} N_{1}(l, y, r)} C_{1}(l, y) \tag{1}
\end{equation*}
$$

where $N_{1}(/, y, r)$ is the number of fish born in year $r$ in length class / on J anuary 1 of year $y$ just before harvest, $N(/, y, r)$ is the population size immediately after harvest, $C_{2}(/, y)$ is catch in number of length / harvested on J anuary 1 of year $y$. If $N(/, y, r)$ becomes negative, $N(/, y, r)$ is assumed to be 0 .

Natural mortality is assumed to depend on age, and length growth rate depend on length, age and recruitment year.

$$
\begin{equation*}
N_{2}\left(l_{2}, y, r\right)=\sum_{l_{1}} N^{\prime}\left(l_{1}, y, r\right) \exp \left(-M_{a}\right) L_{1}\left(l_{1}, l_{2}, y, r\right) \tag{2}
\end{equation*}
$$

where $N z(I, y, r)$ is the number of fish born in year $r$ in length class / on J uly 1 of year $y$, $M_{a}$ is instantaneous natural mortality for a half year in age $a$ which we can calculate as a difference between $r$ and $y . L_{1}\left(I_{1}, l_{2}, y, r\right)$ is the probability that fish born in year $r$ grow from length $I_{1}$ category to length $I_{2}$ category in the first season of year $y$.

Second season. J apanese longline fishery and all remaining fisheries are assumed to harvest fish on July 1 . As well as in the first season fishery, fishing and natural mortality and growth are modeled as the following.

$$
\begin{align*}
& N^{\prime \prime}(l, y, r)=N_{2}(l, y, r)-\frac{N_{2}(l, y, r)}{\sum_{r} N_{2}(l, y, r)} C_{2}(l, y)  \tag{3}\\
& N_{1}\left(l_{2}, y+1, r\right)=\sum_{l_{1}} N^{\prime \prime}\left(l_{1}, y, r\right) \exp \left(-M_{a}\right) L_{2}\left(l_{1}, l_{2}, y, r\right) \tag{4}
\end{align*}
$$

where $N^{\prime}(/, y, r)$ is the number after the second season fishery, $C_{2}(/, y)$ is the catch number of fish length / in the second season of year $y$, and $\angle_{2}\left(I_{1}, I_{2}, y, r\right)$ is the probability
that fish born in year $r$ grow from length $I_{1}$ to length $I_{2}$ in the second season of year $y$. If $N^{\prime}(/, y, r)$ is negative, $N^{\prime}(1, y, r)$ is assumed to be 0.

## - Objective function

The model is designed to estimate the number of recruitments in each year from 1912 to 2001 to minimize an objective function. The objective function consists of three components; 1) abundance indices from length-based CPUE of J apanese longline fishery from 1969 to 2003, 2) catch-at-age composition in Indonesian fishery for eight spawning seasons (1994/5, 1996/7, 1997/8, 1998/9, 1999/2000, 2000/1, 2001/2, 2002/3) and 3) a penalty term for inter-annual variation of recruitments.

We use length-based CPUE which is standardized by generalized linear model (GLM) explained in the following section.

$$
\begin{equation*}
F_{1}=\sum_{l} w(l) \sum_{y}\left(\ln \operatorname{CPUE}(l, y)-\ln \left(q(l) \sum_{r} N_{2}(l, y, r)\right)\right)^{2} \tag{5}
\end{equation*}
$$

where

$$
\begin{equation*}
q(l)=\exp \left(\frac{1}{n} \sum_{y}\left(\ln C P U E(l, y)-\ln \sum_{r} N_{2}(l, y, r)\right)\right) \tag{6}
\end{equation*}
$$

where $\phi(/)$ is catchability dependent on length and $n$ is the total number of years used in tuning ( $n=35$ ). The previous analysis showed that it was inappropriate to assume equal reliability of all length groups (Kurota et al., 2001). Therefore, as the base case, we regard higher absolute value of CPUE as more reliable information and determine weight $m(/)$ using temporal average of absolute CPUE values in CS assumption described in the following section. This method of weighting was examined in the previous analysis and the result was satisfactory.

Age distribution of Indonesian catch on the spawning ground is assumed to follow to the multinomial distribution.

$$
\begin{equation*}
F_{2}=-w_{a} \sum_{y} \sum_{a} p_{\text {obs }}(y, a) \ln p_{\text {pred }}(y, a) \tag{7}
\end{equation*}
$$

where $p_{\text {obs }}(y, a)$ and $p_{\text {pred }}(y, a)$ represent observed and predicted proportion of age $a$ in
year $y$, respectively and $w_{a}$ is the effective sample size. $w_{a}$ is set 10.0 in the base case. Predicted age distribution is calculated from observed CAL data of Indonesian fishery and predicted age composition in each length class.

A penalty term is introduced for yearly variation of recruitments to provide smoothness in recruits and obtain converged estimates robustly. Recruitment change is assumed to follow the log-normal distribution.

$$
\begin{equation*}
N_{1}(0, r, r)=N_{1}(0, r+1, r+1) \exp \left(\gamma_{r}\right), \quad \gamma_{r} \sim N\left(0, \sigma_{r}^{2}\right) \tag{8}
\end{equation*}
$$

Then, the penalty term is described as:

$$
\begin{equation*}
F_{3}=\sum_{r} \frac{\gamma_{r}{ }^{2}}{2 \sigma_{r}{ }^{2}} \tag{9}
\end{equation*}
$$

where $\sigma_{r}$ is dependent on recruitment year. Default values are $\sigma_{r 1}=0.1$ for 1912 to 1951, $\sigma_{r 2}=0.5$ for 1952 to 1968 and $\sigma_{r 3}=5.0$ after 1969. A small value for early times is necessary to obtain converged estimates, because there is little information for tuning the model. Objective function to minimize is sum of $F_{1}, F_{2}$ and $F_{3}$.

$$
\begin{equation*}
F=F_{1}+F_{2}+F_{3} \tag{10}
\end{equation*}
$$

## - Other assumptions

The model is calculated under the following other assumptions.

- Fish life span is up to age 40. Plus-group is not applied.
- Fish grows up to age 21 and the length is constant afterward.
- $M_{a}$ is half of that in V6 option (Anonymous, 1998).
- Maturity is age-dependent process and age-at-maturity is age 10. Spawning biomass is derived from age-weight relationship estimated by J. N. I anelli in 2001.
- No fishery for SBT before 1951.
- Model calculation begins in 1912 so that fish population in 1951 can cover all age range. Recruitments before 1968 are constrained within a range of $1.0 \mathrm{e}+6$ and $1.0 \mathrm{e}+8$. Recruitments after 1969 are also limited within a range of 0 and $1.0 \mathrm{e}+8$.
- CAL is treated in units of $10 \mathrm{~cm}(0-9,10-19, \ldots, 190-199,200+)$.

## Data preparation

CAL data of Australian surface fishery was prepared from bi-monthly CAL data after 1952. Catch between July 1 and J une 30 of the following year was considered to be taken on J anuary 1 . We did not adjust length according to actual time of catch.

CAL in Indonesian fishery at the spawning ground before 1993 was derived from total catch in weight of each season (from J uly to J une), average weight of a fish from the 1993/4 and 1994/5 seasons, and average length frequency for the two seasons, which were provided by Australian scientists. CAL after 1994 was calculated from total catch in number and length frequency in each year, which were estimated by CSIRO and IOTC. We also used age composition data of Indonesian catch as a tuning index for eight seasons (from 1994/5 to 2002/3 except 1995/6).

CAL data by J apanese longline and miscellaneous fisheries was gathered from CAL of LL1, LL2, LL3 and LL4 (except Indonesian longline) prepared for the operating model of the management procedure development. Historical J apanese data before 1994 was updated and CAL in the second season was different from that used at the 2001 SAG meeting. Table 1 showed all CAL data each season used in this study.

## Length-based longline CPUE

Length-based CPUE time series were estimated for tuning indices. The data source used in this estimation is CAL information (1969-2003) by $5 \times 5$ degree square/ monthly basis in NRIFSF database. This data set includes only J apanese commercial longline fisheries data, and does not include data for joint venture fisheries with Australia and New Zealand.

Length groups used for the abundance index were defined through graphical examination of CPUE trends for length classes of every 10 cm interval by month. The CPUE examined here was monthly average of nominal CPUE of $5 \times 5 /$ month. These 10 cm-interval length classes that showed similar CPUE trends to one another were lumped together, and eight length groups were defined for the abundance index estimations. The defined length groups were " $60-80$ ", " $90-100$ ", " $110-130$ ", " $140-150$ ", " 160 ", " 170 ", " 180 ", and " $190+$ ". For example, length group " $60-80$ " includes fish between 60 cm and 89 cm and so on.

The data set prepared for Generalized Linear Model (GLM) standardization contains catch numbers for these length groups and corresponding effort by year, quarter, month, SBT statistical area, and $5 \times 5$ latitudellongitude. The following model was fitted to the data:

$$
\begin{align*}
& \ln \left(\text { CPUE } E_{\text {yqmal }}+\xi\right) \\
& \qquad=\mu+Y+Q+M+A+L+Y^{*} A+Q * A+Y * Q+\varepsilon \tag{8}
\end{align*}
$$

where
In is the natural logarithm,
CPUE is the nominal CPUE,
$y \quad$ is $y$-th year (1969-2003),
$q$ is q-th quarter (2 and 3 ),
m is m-th month (April-September),
a is a-th SBT statistical area (4, 5 and 6, 7, 8, 9),
$1 \quad$ is l-th latitude (30, 35, 40, 45, 50),
$\xi \quad$ is $10 \%$ of the mean nominal CPUE (cf., Campbell et al. 1996),
$\mu \quad$ is the mean CPUE (the intercept term),
$Y$ is the effect of year,
Q is the effect of quarter,
$M$ is the effect of month,
A is the effect of SBT statistical area,
L is the effect of latitude,

* indicates the interaction term, and
$\varepsilon$
is the error term, $\in \sim N\left(0, \sigma^{2}\right)$.

We prepared two set of time series, proxies of the B-ratio and geostatistical CPUE models, which were corresponding to the two interim abundance indices (wo.5 and wo.8) (Tsuji et al., 2004). However, we used only the geostatistical CPUE for tuning the model in the base case (Fig. 1). Because small fish below 25 kg (ca. 120 cm ) were released in 1995 and 1996 (Itoh et al., 1998), we did not used CPUE of 60-80, 90-100, 110-130 length groups in the two years as tuning index.

## Construction of length transition matrix

Length transition matrix was developed to reflect length variation observed in the direct aging study (Gunn et al., 1997). Fish growth was assumed as the following.

$$
\begin{equation*}
l(t+1)=l(t)+\Delta l(a)(1+\varepsilon) \tag{9}
\end{equation*}
$$

where $/(t)$ is individual length in time $t, \Delta l(a)$ is average growth for a half year in age $a$ of the 1980 recruitment, which is estimated by J. N. Ianelli, $\varepsilon$ is variance following the normal distribution (average 0 , sd $\sigma$ ).

Variance of growth for a half year was estimated by the Monte Carlo method. We simulated 5000 individuals' growth until age 21 at half-year interval and looked for $\sigma$ fitting to length variation data of Gunn et al. (1997) by the least square method. It was found that the value $\sigma$ of 0.115 gave the best fit to the observed data.

We fixed $\sigma$ at 0.115 and simulated 5000 individuals' growth again in order to calculate probability of growth from length class / to length class $/, /+1, /+2, \ldots$ in age $a$. Because age-growth relationship of SBT was known to change in 1970's, transition matrices were constructed for each recruitment by applying different $\Delta l(a)$ corresponding to the sets of age-length relationship agreed to use in the 2001 assessment. $\Delta l(a)$ for each year and age was derived from cut-point table estimated by J. N. Ianelli.

## Results and Discussion

## - Base case

Fig. 2 showed model predictions in the base case, which was applied default assumptions (also see Table 2). Recruitments were estimated after 1912, but estimates before 1950s were strongly dependent on model hypothesis because there was little available information for tuning. Thus, we chiefly examined estimates of recruitment and spawning biomass after 1952 here.

Recruitments were at the peak in late 1950s and late 1960s, and they had declining trend until mid-1980s. Afterwards, they fluctuated and did not show a particular trend, but they decreased significantly after 1999 and reached the historically lowest level, although error bands of the estimates were very large. Spawning biomass was at the peak in 1950s and decreased up to mid-1990s in a general term. However, spawning biomass became almost constant in recent years at $30 \%$ of the maximum level. We also found a positive relationship between recruitments and spawning biomass, but the function form did not look clear.

Predicted CPUEs were reasonably well fit to observed data in length groups 90-100, 110-130 and 140-150, which had high weighting values as tuning indices. However, model predictions failed to explain CPUE trends of other size groups. This might indicate that there is inconsistency of CPUE among length groups, which our
previous analysis also showed (Kurota et al., 2001). The model also predicted age composition on the spawning ground satisfactorily.

## - Exploration of alternative formulations

Effective sample size $\mathrm{w}_{\mathrm{a}}$ of spawning ground age composition. We checked inconsistency between stock trend indicated by the longline CPUE data and that by the age composition data in the spawning ground by changing effective sample size $w_{a}$, which meant relative weight of the age composition data in the objective function. As wa became larger, recruitments and stock biomass were estimated to be lower (Fig. 3). Predicted spawning age compositions were also better fit to the data. However, the differences were very small except when the value was 5.0. Therefore, we considered that there was not large inconsistency between the spawning age composition and the CPUE information.

Relative weight w() of each length group. In the base case, we regarded higher absolute value of CPUE as more reliable information and determined weight $m /$ using temporal average of absolute CPUE values. We explored two other assumptions to examine effects of relative reliability of longlineCPUE data among length groups; (1) all length groups have the same reliability and (2) reliability is proportional to the square root of temporal average of absolute CPUE values.

When all length groups had the same weight, estimated results were different significantly from those in the base case (Fig. 4). Temporal pattern of recruitments was somewhat similar to that in the base, but the absolute values were much larger. Estimates of spawning biomass were also quite different. However, even if the same reliability was assumed, model prediction failed to explain high CPUE trend of Iarge length groups over 140 cm in early 1970s, as our previous analysis also showed. In addition, fitting to the age composition of Indonesian catch was worse and the stock-recruitment relationship looked strange. Therefore, we considered that this equal reliability assumption was not acceptable. When relative weights were proportional to the square root of the absolute CPUE values, the result was between the base case result and the result in the equal reliability assumption. We considered that this assumption was not better than the base case from the viewpoint of the objective function value (Table 3).

Age of maturity. In this model, any relationship between recruitments and spawning
biomass was not assumed and any index for matured adults was not used in tuning. Therefore, age of maturity did not affect estimation of recruitment itself (Fig. 5). However, historical trends of spawning biomass were different among assumptions on age of maturity. As maturity age became older, spawning biomass decreased more severely relative to that before fishing started (Table 1).

Penalty for recruitment variability, $\sigma_{r 2}$ : This parameter was originally introduced to restrict temporal change of recruitment from 1952 to 1968 and obtain converged estimates more robustly. We found that this parameter influenced significantly on recruitments and stock biomass before fishing started, but those estimates after 1970s were not different among assumptions (Fig. 6). This might indicate lower reliability for estimates in old times.

Data update. Some data were revised and updated for stock assessments in 2004 as follows:
a) revision of historical catch-at-age data and CPUE of J apanese longline (from 1965 to 2000)
b) addition of three years data of all fisheries (from 2001 to 2003)
c) recal culation of Indonesian catch data (from 1976 to 2003)

To examine influences of these data change, we compared with results in using (1) all new data up to 2004 (base case), (2) old data up to 2001 without any revision and recalculation ("2001old"), and (3) new data up to 2001 including revision of historical data and recalculation of Indonesian catch ("2001new"). Estimation model used here was a new version with a penalty term for recruitment variation.

Revised and recalculated historical data had some effects of recruit estimates before 1960s and in 1990s (Fig. 7). Estimated stock biomass using new data was lower than using old data, although the difference became smaller recently. Comparison between the base case and the "2001new" showed that data addition up to 2004 resulted in higher recruitments in mid-1990s. This is because CPUEs of middle size fish were high these three years. Difference in biomass in 1950s was also found between them. We considered that this is because influence of the age composition of Indonesian catch in the "2001 new" was small relatively in the objective function since the number of the age composition data decreased from eight to five. Therefore, we examined a condition that $w_{a}$ was 16.0 and found that the results were quite similar between the base case and the "2001 new_wa16" except recent recruitments.

## Acknowledgments

We are grateful to Ann Preece for providing us with Indonesian catch data.

Fig. 2. Estimates of recruitment (1952-2001 and 1931-2001), spawning biomass (1952-2004) and stock-recruitment relationship (1952-2001), and fit to J apanese Iongline CPUE data and age composition of Indonesian catch in the base case (open circle: observed data, line: prediction). Error bands represent one standard error of the estimates.

Fig. 3. Effects of $w_{a}$ on estimates of recruitment, spawning biomass, stock-recruitment relationship, and fit toJ apanese longline CPUE data and age composition of Indonesian catch (open circle: observed data, line: prediction).

Fig. 4. Effects of $w(I)$ assumption on estimates of recruitment, spawning biomass, stock-recruitment relationship, and fit to J apanese longline CPUE data and age composition of Indonesian catch (open circle: observed data, line: prediction).

Fig. 5. Effects of age of mature on estimates of recruitment, spawning biomass, stock-recruitment relationship, and fit to J apanese longline CPUE data and age composition of Indonesian catch (open circle: observed data, line: prediction).

Fig. 6. Effects of $\sigma_{r 2}$ on estimates of recruitment, spawning biomass, stock-recruitment relationship, and fit to J apanese longline CPUE data and age composition of I ndonesian catch (open circle: observed data, line: prediction).

Fig. 7 Effects of used data set on estimates of recruitment, spawning biomass, stock-recruitment relationship, and fit to Japanese longline CPUE data and age composition of Indonesian catch (open circle: observed data, line: prediction).
